Abstract—Many program analyses require statically inferring the possible values of composite types. However, current approaches either do not account for correlations between object fields or do so in an ad hoc manner. In this paper, we introduce the problem of composite constant propagation. We develop the first generic solver that infers all possible values of complex objects in an interprocedural, flow and context-sensitive manner, taking field correlations into account. Composite constant propagation problems are specified using COAL, a declarative language. We apply our COAL solver to the problem of inferring Android Inter-Component Communication (ICC) values, which is required to understand how the components of Android applications interact. Using COAL, we model ICC objects in Android more thoroughly than the state-of-the-art. We compute ICC values for 460 applications from the Play store. The ICC values we infer are substantially more precise than previous work. The analysis is efficient, taking slightly over two minutes per application on average. While this work can be used as the basis for many whole-program analyses of Android applications, the COAL solver can also be used to infer the values of composite objects in many other contexts.

I. INTRODUCTION

Program analyses sometimes need to statically infer the possible values of object fields. Such a program analysis that has recently received interest [11], [15], [34] is the inference of messages communicated between Android applications. The components of Android applications can interact with one another using platform-specific constructs. This Inter-Component Communication (ICC) facilitates the reuse of functionality, both within and between applications. For example, an application may need to render a map centered on specific geographic coordinates. In Android, this application simply needs to send an ICC message, which will be relayed to an appropriate target by the operating system. The target will then render the map based on passed values.

This development model potentially presents concerns. First, exposed application components may be activated in unexpected ways, leading, for example, to privilege escalation attacks [14], [25]. Second, ICC messages can be intercepted by malicious recipients, with consequences ranging from data leaks [8] to piracy [29]. Finally, since information may flow between components, secure information flow analysis must account for inter-component flows. Without ICC analysis, in order to remain conservative, static taint analyses in Android have to assume that any data coming from another component is tainted [1]. With ICC analysis, such a taint analysis can precisely determine if inter-component links carry tainted data. Thus, ICC analysis has proven very valuable in many contexts such as information flow analysis [22], [24], [38], [41], patch generation for privilege escalation vulnerabilities [42] and detection of stealthy behavior [18].

In order to infer facts about interactions between components, we need to find all possible values of the fields of ICC objects at program points where message passing occurs. Unfortunately, existing studies of application interfaces are limited. The Epicc tool [34] tries to determine the specifications of ICC interfaces. Unfortunately, it only addresses Intent messages and a small subset of URI messages for which all fields are constant values. Adding complete support for URIs using the same approach as for Intents would result in a significant increase in the complexity of the formulation and implementation of the data flow functions. While this is possible in theory, it is not feasible in practice. Apposcopy [15] also infers Intent values but does not compute all fields of an Intent. In particular, similarly to Epicc URI data is not inferred.

In this paper, we define the problem of Multi-Valued Composite (MVC) constant propagation. Unlike most constant propagation analyses, we attempt to find all possible values of objects of interest at important program points, making our analysis multi-valued. Our analysis targets composite constants, i.e., we determine the values of complex objects that may have multiple fields, taking the correlations between fields into account. Problems are specified using the COAL declarative language. We design a COAL solver, which takes COAL specifications and programs as input and outputs composite constant values at program points of interest. In order to automatically generate data flow functions, it utilizes the concept of field transformers, which express how fields are changed by program statements.

While MVC constant propagation was motivated by Android ICC analysis, this work applies to a wide variety of static program analyses where the range of values of objects needs to be determined. It is valuable in various areas such as software security, maintenance and modeling. It can apply to many object oriented programming languages.

As an application of our composite constant propagation solver, we implemented and evaluated IC3, a new tool for Android ICC analysis. In the COAL language, we modeled all ICC messages with about 750 lines of COAL specification. Since Android ICC messages heavily rely on strings of characters, we devised and implemented a string analysis that is both efficient and more precise than the one in Epicc. We computed ICC values in 460 applications from the official Play store.
Components can communicate with one another using two kinds of objects. Uniform Resource Identifiers (URIs) are used to address data in Content Providers. Intent object are used in all other cases. The target component of an Intent can be specified by explicitly naming it, or it can be determined automatically by the operating system based on the fields of the Intent. An Intent resolution procedure maps a given Intent to possible targets. Several fields of an implicit Intent are used to match it with potential targets. The action field represents the operation that the receiving component should perform. The categories field adds information about the component that the system can use. For instance, the system places components with the LAUNCHER category in the main application launcher. The data field includes data that the receiving component should act on. It has the form of a URI.

Components can subscribe to receive implicit Intents by specifying Intent Filters, which describe the actions, categories and data of the Intents that should be addressed to them. Most Intent Filters are specified in the manifest file that is included with every application.

Figure 1 shows a representative example of Android ICC. In this figure and in the remainder of this paper, we abbreviate string values for ease of exposition. Figure 1(a) shows a method that sends an Intent in order to render a map centered at given coordinates. An Intent intent is created. Its action is set to VIEW, which is a generic action used to display many kinds of data. The data of the Intent is defined to be a URI with the geo scheme followed by coordinates. When the startActivity() framework method is called, the operating system (OS) resolves potential target components, prompting the user to choose a recipient if several components match.

Figure 1(b) is a component declaration as it can be found in an application manifest. The activity element (Line 1) declares that the application contains an Activity component with name MapRenderingActivity that includes a single Intent Filter. The action line specifies that the action field of Intents received by the component should have value VIEW. The data declaration at Line 4 specifies that any received Intent should carry data in the form of a URI with a geo scheme. Finally, the category line declares that received Intents can carry the DEFAULT category. This category is added by the OS to implicit Intents targeting Activities, such as the one on Line 6 of Figure 1(a). Therefore, MapRenderingActivity could receive the Intent created in Figure 1(a).

In order to statically know how application components communicate with one another, we need to determine the values of ICC objects at message-passing program points. For example, in Figure 1(a), we want to know all the possible values of intent at statement startActivity(intent). Objects of interest are Intents, Intent Filters and URIs. It is very challenging to write data flow models separately for all of these. That is why previous work [34] has not properly handled URIs, which has two negative consequences. First, interactions with Content Providers cannot be determined. Second, the data field of Intents cannot be known, which significantly limits the Intent resolution process. Any field that cannot be known results in a loss of precision. For example, mapping the Intent from Figure 1(a) with the component from Figure 1(b) requires knowing the action and the URI data of the Intent. When the data field is not known, any attempt to resolve the possible targets of intent from Figure 1(a) has to conservatively assume that the data field can take any value. Figure 1(c) declares a dialer Activity DialerActivity. It is similar to MapRenderingActivity, except that it adds support for a DIAL action and it handles tel URI schemes. Because of

```java
1  void map(float latitude, float longitude) {
2    Intent intent = new Intent();
3    intent.setAction("VIEW");
4    Uri geoUri = Uri.parse("geo:" + latitude + "," + longitude);
5    intent.setData(geoUri);
6    startActivity(intent); }
```

![Example Intent and Intent Filter used for rendering a map](image)
public class Intent {
  private String action;
  private Set<String> categories = new
  HashSet<>();
  private String data;
  private String mimeType;
  public void setAction(String act) {
    this.action = act;
  }
  public void addCategory(String cat) {
    this.category = cat;
  }
  public void setDataAndType(String d, String t) {
    this.data = d;
    this.mimeType = t;
  }
  public void setData(Uri u) {
    this.data = u.getData();
    this.mimeType = null;
  }
  public void setData(String d) {
    this.data = d;
  }
  public void addCategory(String cat) {
    this.category = cat;
  }
  public void setDataAndType(String d, String t) {
    this.data = d;
    this.mimeType = t;
  }
  public void setData(Uri u) {
    this.data = u.getData();
  }
  public void setData(String d) {
    this.data = d;
  }
  return this.data;
}

class Intent {
  String action; String categories; String data; String mimeType;
  mod <Intent: void setAction(String)> {
    0: replace action;
    mod <Intent: void addCategory(String)> {
      0: add categories;
    }
  mod <Intent: void setDataAndType(String,String)> {
    0: replace data;
    1: replace mimeType;
  }
  mod <Intent: void setData(Uri)> {
    0: replace data;
  }
  source <Uri: String getData(String)> {
    data; }
  clear mimeType;
  query <Context: void startActivity(Intent)> {
    0: type Intent; }
}

class Uri {
  String data;
  mod <Uri: void setData(String)> {
    0: replace data;
  }
  source <Uri: String getData(String)> {
    data; }
}

(a) Simplified Intent and Uri classes. The real ones comprise 2,000 and 1,200 SLOC, respectively.
(b) Message-passing code. We assume that the mimeType argument may have value either image/jpg or image/*.

d) Possible values of the fields of intent at the startActivity() call. We have abbreviated the URI strings for space reasons, however our system would infer complete strings. Value 1 is for the first branch after the if statement (Lines 6-8 in (b)). Values 2 and 3 account for the fall-through branch of the if statement, where argument mimeType may have two different values.

![Fig. 2. Running example.](image)

its inability to infer Intent URI data, the current state-of-the-art [34] would infer that both MapRenderingActivity and DialerActivity can receive the Intent. In reality, only the former is able to do so. Thus, more precision is needed to avoid such false positives.

We address this issue in this paper. In Sections III through VI, we introduce a novel approach to statically infer the set of values that objects can take. In Section VII, we apply this approach to the problem of inferring Android ICC values.

### III. OVERVIEW

#### A. The MVC Constant Propagation Problem

Consider OBJ an object of type class Pair\{int X; int Y\}. Assume that at some program location OBJ can be either \((X, Y) = (1, 10)\) or \((2, 20)\). We would like an analysis that can determine this fact. Classical constant analysis applied for each field fails at determining a useful value because none of the fields is the same constant across all paths. Multi-valued constant analysis could determine that OBJ.X \(\in \{1, 2\}\) and OBJ.Y \(\in \{10, 20\}\). These constraints accurately describe the individual fields, but they allow for imprecision in the object, because they allow the possibility that OBJ = \((1, 20)\). We define the Multi-Valued Composite (MVC) constant propagation problem to be the problem of determining the set of values that an object viewed as a tuple (such as \((X, Y)\)) can have. Note that the above multi-valued constant analysis applied to individual fields is a possible solution, it may just not be precise enough for certain analyses. We will show how to efficiently find more precise solutions.

We now introduce a running example that will be used throughout. Figure 2(a) shows code for a hypothetical Intent class that contains data used for passing messages between application components. It uses a data field which is copied from a Uri object, for which code is also shown in Figure 2(a). Figure 2(b) defines method sendMessage(), which we assume to be called as part of an Android application. This method creates an Intent object and sets its action field. Then, depending on the value of a Boolean, one of two things can happen. In the first branch after the if statement (Lines 6-8), the result is sent to another component using the startActivity() method.

The data flow problem we are solving is to determine all the possible values of the fields of intent at the call to startActivity(). In our propagation framework defined below, the problem can be specified using COAL, a declarative language we designed for this purpose. The function of COAL (COnstant propAgation Language) is to specify Multi-Valued Composite (MVC) constant propagation problems. It specifies the types of variables for which values should be inferred.
The COAL language is recognized by our COAL solver, which outputs solutions for many propagation problems solely from their COAL specification and an input program.

Figure 2(c) shows how to specify the problem with our framework using COAL. The COAL specification is manually written once and it can subsequently be used to solve the same problem for an arbitrary number of applications. It is composed of field declarations, modifiers and a query. The field declarations specify the fields that are being tracked and their type. Note that, for each field, we keep track of sets of values, even though the field declaration only specifies the type of each individual field value. The first modifier indicates how the \texttt{setAction}() method influences the modeled value of an Intent object. A modifier specification starts with the signature of the modeled method. Each line in a modifier declaration is an argument whose value is used to modify the Intent value. Each argument declaration is composed of several attributes. An integer declares the position of the argument in the array of arguments to the method, with indices starting at 0. After the argument index, an operation and a field are declared. They describe both the field that is modified by the method and how it is modified. For example, in the \texttt{setAction()} modifier, \( \theta \): \texttt{replace} \texttt{action} means that the \texttt{action} field is replaced with the value of the first argument to \texttt{setAction}(). Other modifiers are declared in a similar manner, except when the type of an argument is a class that is modeled with COAL. In that case, a \texttt{type} attribute is used in order to specify which field of the argument object is used. For example, in the \texttt{setData()} modifier, the \( \theta \): \texttt{replace} \texttt{data}, \texttt{type} \texttt{Uri:} \texttt{data} argument means that the \texttt{data} field of the \texttt{Uri} argument is used to replace the \texttt{data} field of the Intent being modified.

The query statement indicates that we are querying the solution at all calls to \texttt{startActivity}(). Similarly to the modifier declaration, we specify a list of arguments. They describe the arguments whose value we would like to query. In this case, it is the first argument (as described by the \( \theta \) attribute), which is an Intent object. The source at Line 22 indicates how a field value flows out of an object. This is useful when the value subsequently flows into a COAL modifier, since the COAL solver can then infer the correct value.

Figure 2(d) shows the expected result of our analysis. We want our analysis to recover the three possible values of Intent \texttt{intent}. These values correspond to all possible execution paths of the program from Figure 2(b). We wish to recover exactly these possible values, and we do not want all the possible combinations of fields. For example, it is not possible in our problem to have an Intent value with category \texttt{BROWSABLE} and MIME type image/jpg. As a result, our analysis does not simply track fields individually as separate variables, but rather propagates composite constants.

B. MVC Constant Propagation Analysis

Figure 3 shows a general overview of the analysis process that takes an application as input and outputs the values of composite objects. It starts by converting the program to an intermediate representation that is suitable for further analysis (Step 1). It then generates an Interprocedural Control Flow Graph (ICFG) (Step 2). An ICFG is a collection of CFGs of all the procedures in the program connected with each other at procedure call sites. This includes building a call graph for the entire program. Finally, the actual MVC data flow analysis takes place in Step 3 and outputs the MVC constant values.

Existing work [1], [30] can perform Steps 1 and 2. Therefore, the scope of this paper is limited to the MVC data flow analysis (Step 3), which is performed using our COAL solver. Figure 4 depicts a more detailed overview of the COAL solver, which takes two inputs. First, it uses the ICFG of the program being analyzed. Second, it takes a COAL specification for the problem being solved. This COAL specification describes the structure of the composite objects for which constant propagation should be performed. It also describes the methods that can modify these objects and the program locations where the constants should be computed. The specification is written using the COAL language, which allows MVC constant propagation problems to be specified easily. It should be noted that, for a given problem, the COAL specification need only be written once, after which an arbitrary number of programs can be analyzed.

For each program, the COAL specification is parsed to build a model of the problem by creating problem-specific lattices of values and data flow functions. These are input with the ICFG into a solver for Interprocedural Distributive Environment (IDE) problems [36]. We present the generic IDE model for constant propagation in Section V. Finally, since the values of arguments to functions have to be known, we use argument value analyses (e.g., integer and string analyses) to generate the data flow functions.

The IDE solver outputs the analysis results. The COAL language allows specification of program points of interest (queries) where the MVC constant values should be computed. This is useful in cases where the program points of interest are known in advance. In other cases, we also allow lower-level queries to the IDE solver as part of the COAL solver API. The results can then be output in a simple text format or accessed using a programmatic interface (API).

Note that it is possible to write MVC data flow models for individual classes in an \textit{ad hoc} manner without using an MVC constant solver. However, given the complexity of a typical MVC model, doing so is time consuming and prone to errors. In contrast, the approach we present relies on a
The model for a given object is composed of field declarations, modifiers, constants and sources. Queries can also be specified using the COAL language to automatically generate semilattices of values and data flow functions.

A simplified grammar for this language is presented on Figure 5. The { } characters symbolize repetition, while [ ] characters surround optional parts of a production.

The model for a given object is composed of field declarations, modifiers, constants and sources. Queries can also be specified using the COAL language to automatically generate semilattices of values and data flow functions.

Field declarations - A field declaration specifies a field that is part of the modeled class. It describes a data type and a name for the field. In Figure 5, we use non-terminals (type) and (field name) to represent valid types and field names.

Modifiers - Modifiers represent method calls where constant values flow to the modeled object. The specification of the modifiers comprises a method signature (method sig) that identifies the method of interest. It also includes a set of arguments that describe how the method arguments are used to modify the fields of the modeled object. A modifier argument has several attributes. An argument index identifies the method argument of interest. In some cases, several arguments contribute to the value of a single field. That is why the language supports sets of argument indices. A field operation to be performed is also specified. This allows the solver to create appropriate data flow functions. Natively supported field operations are add (add argument value to the field), remove (remove argument value from field), replace (replace field with argument value) and clear (clear field value). A modifier specification also includes a field name that identifies the field being modified. In the case where an argument is a class modeled with COAL, an argument type and additional field name are specified. This indicates to the solver that the value of a field of a modeled class flows to the object being modified.

Constants - Many languages allow the specification of constants (e.g., static final fields in Java). The constants of a class are initialized in the class initializer the first time the class is referenced. A naive way to deal with constants would consist in tracking the constant creation and initialization as it is done for all modeled objects. We would then propagate them throughout the entire program at the cost of performance. As a performance optimization, we allow constant modeled objects to be specified in COAL. Where these values are used, the COAL solver uses the specified value.

Sources - Sources model the case where a modeled field value flows to an argument value. For example, the source at Line 22 of Figure 2(c) defines the COAL solver to infer that the data field of the Uri object flows to the intent variable. Using this information allows the solver to infer the correct value for the data field of intent.

Queries - Queries specify statements of interest where modeled values should be determined.

The MVC constant propagation problem from Figure 2(b) can be solved by inputting the program and the specification from Figure 2(c) into our COAL solver. Alternative methods such as code annotations could be used to specify these problems. However, our approach specifies all analysis parameters in a single location and does not require the source code of the modeled objects. Annotations, on the other hand, would require source code and they would have to be spread over the modeled code. In our motivating example of Android, this implies spreading specifications over thousands of lines code.

V. A GENERIC MODEL FOR MVC CONSTANT PROPAGATION

The purpose of the COAL language and the associated constant propagation solver is to determine the possible values of composite objects by only defining a COAL specification. The COAL solver automatically converts the COAL specification to an instance of an Interprocedural Distributive Environment (IDE) problem, using the model defined in Section V. Given an IDE problem, existing algorithms can compute a solution [36]. This section presents the analysis domain and a space F of functions that model the influence of COAL modifiers. They will subsequently be used in Section VI to automatically build reductions to IDE problems. Interested readers are referred to the technical report [31] for a more detailed presentation.
A. The L Semilattice of Values

For any set \( X \), we denote the power set of \( X \) by \( 2^X \) and the set of functions from \( X \) to \( X \) by \( X^X \). We are trying to determine the value of an object with \( n \) fields, taking values in finite sets \( V_1, \ldots, V_n \). If field \( i \) has a container type (e.g., set of integers), \( V_i \) is the contained type (e.g., integer). For \( i \in \{1, \ldots, n\} \), let \( P_i = 2^{V_i} \cup \{\omega\} \), where \( \omega \) represents an undefined value. Let \( B = P_1 \times \cdots \times P_n \). We define \( L = \langle 2^B, \subseteq \rangle \) as a join-semilattice with a bottom element \( \bot \). The join operation on \( L \) is the set union \( \cup \). The top element of \( L \) is the set of all elements in \( B \).

Sets \( V_1, \ldots, V_n \) are the domains of the field values we are trying to determine. For example, \( V_1 \) could be the set of constant strings of characters in the program. A value in \( B \) represents a value as it is seen on a single path. Finally, values in \( L \) represent values of objects, taking into account several paths of a program. Note from the definition of \( P_1, \ldots, P_n \) that we keep track of sets of values, even for scalar fields. A scalar is simply represented by a set with a single value.

Let us consider the example from Figure 2(a). We are interested in four fields: action, categories, data and mimeType. Let \( S \) be the set of string constants in the program. In this case, we consider all \( P_1 = P_2 = P_3 = P_4 = 2^S \cup \{\omega\} \). In other words, we consider all four fields to take values in the power set of \( S \). We have \( B = P_1 \times P_2 \times P_3 \times P_4 \) and \( L = \langle 2^B, \subseteq \rangle \).

In method `sendMessage()`, the value associated with the `intent` variable is initially \( \bot \) before Line 2. Line 2 transforms this value to \( \{\varnothing, \varnothing, \varnothing, \varnothing\} \). Right after Line 3, the value is \( \{\{\{\text{VIEW}, \varnothing, \varnothing, \varnothing\}\}, \varnothing, \varnothing, \{\text{image/jpg}, \{\text{image/*}\}\}\} \).

B. Transformers on \( L \)

The intuition behind the COAL language is that each argument in a COAL modifier represents the influence of the method call on a field. Accordingly, we introduce transformers that are defined at the granularity of fields. In this section, we assume that the value of `uri` is available wherever needed. We revisit this assumption in Section VI-C.

**Definition 1** - For \( i \in \{1, \ldots, n\} \), we define \( F_i \) a non-empty subset of \( P_i \) closed under composition. Each \( \phi \in F_i \) is called a field transformer.

In this paper, we consider field transformers \( \phi \) such that:

- **Type (1):** \( \phi(\omega) = \omega \) and for all \( X \in P_i \) such that \( X \neq \omega, \phi(X) = (X - \text{KILL}) \cup \text{GEN} \), for some constant sets \( \text{GEN} \) and \( \text{KILL} \) in \( P_i \). Such a function will also be denoted as \( \phi = \phi^\text{GEN} \). This is used for the add and remove field operations in COAL.

- **Type (2):** For all \( X \in P_i \), \( \phi(X) = \text{GEN} \), for some \( \text{GEN} \) in \( P_i \). This case is also denoted by \( \phi = \phi^\text{GEN} \). This is used for the replace and clear field operations in COAL.

It is easy to verify that the set of such field transformers is closed under composition.

Let us denote the identity field transformer by \( id \). We have \( id = \phi^\varnothing \). The important idea is that each modifier argument in COAL is mapped to a single field transformer. For example,
Algorithm 1 Generate functions in $F$ from COAL modifiers.

1: procedure GENERATEFUNCTION(modifier, statement) 2: \textbf{result} := $id_l$ 3: \textbf{for} all arguments \textbf{arg} in \textbf{modifier.args} do 4: \textbf{values} := null 5: if \textbf{arg.number} != null then 6: \textbf{values} := GETARGUMENTVALUES(statement, \textbf{arg.number}, \textbf{arg.type}) 7: \textbf{arg.function} := null 8: if \textbf{values} != null then 9: \textbf{for} all argument values \textbf{value} in \textbf{values} do 10: \textbf{current} := BUILDFUNCTION($arg.op$, \textbf{value}, \textbf{arg.field}) 11: if \textbf{arg.function} = null then 12: \textbf{arg.function} = \textbf{current} 13: else 14: \textbf{arg.function} = \textbf{arg.function} \cup \textbf{current} 15: end \textbf{if} 16: \textbf{arg.function} := BUILDFUNCTION($arg.op$, null, \textbf{arg.field}) 17: \textbf{result} := \textbf{result} \cup \textbf{arg.function} 18: return \textbf{result}

flow fact. An environment is a function from $D$ to $L$, where $L$ was introduced in Section V-A. The set of environments is $E$. A join operation $\sqcup$ is defined on $E$ such that, for any $e_1,e_2 \in E$ and $d \in D$, $(e_1 \sqcup e_2)(d) = e_1(d) \cup e_2(d)$. Environment transformers are used to model the influence of program statements on the values of variables. They are functions from $E$ to $E$. For example, before a program statement $s$, the values associated with each variable of interest are given by environment $e_1 \in E$. Statement $s$ transforms $e_1$ to a new environment $e_2 \in E$, which is modeled by an environment transformer $t$ such that $e_2 = t(e_1)$. The IDE framework requires that environment transformers be distributive. An environment transformer $t$ is said to be distributive if, for every $e_1,e_2,\cdots \in E$ and for any $d \in D$, $(t(e_1))(d) = \sqcup(t(e_i))(d)$.

The main function of the COAL solver is to turn COAL specifications into distributive environment transformers. We can show that the functions in $F$ are distributive and that they can be used to easily build distributive environment transformers [31], which ensures the correctness of our approach.

B. Generating Functions in $F$

Since producing environment transformers from functions in $F$ is trivial, this section addresses how the COAL solver builds elements of $F$ from COAL specifications. Algorithm 1 is used by the COAL solver to generate a function in $F$ from a statement and a modifier specification for the statement. It computes functions in $F$ for each argument and composes them (recall from Proposition 1 that $F$ is closed under composition). A modifier argument $arg$ has several attributes: (i) an operation $op$, which is performed by the modifier method, (ii) an argument number $number$, which indicates the position of the arguments of interest in the modifier method, (iii) an argument type $type$, which can be declared as part of the field declaration (see Line 2 of Figure 2(c)) and (iv) field, the index (or the name) of the modified field.

We assume the existence of a procedure GETARGUMENTVALUES, which computes the possible values of a method argument, given an invoke statement, an argument number and an argument type. For most value types, this procedure simply traverses the interprocedural control flow graph starting at the method call looking for assignments to the variable that is used as an invocation argument. For string arguments, we use the analysis described in Section VII-A. Note that the argument type is needed by the COAL solver to select the argument analysis that should be used. We also assume that there is a procedure BUILDFUNCTION that generates a function in $F$ given an operation, an argument value and a field. In the interest of space, we only summarize its main steps. It starts by generating a field transformer $\phi$ using the operation and the argument value. The field index (or name) allows the creation of a function $l \in L$ of the form: $l = id \times \cdots \times id \times \phi \times id \times \cdots \times id$. The corresponding function in $F$ is simply $\{l\}$. When a modifier method argument may have several values resulting in possible functions $f_1,\ldots,f_n$, we compute $f_1 \cup \cdots \cup f_n$ (Line 14).

To illustrate this procedure, let us consider Line 11 of Figure 2(b). The COAL solver determines that this is a modifier with two arguments (see Figure 2(c) Lines 8-10). Considering the first argument $\theta$: replace data and given the fact that $data$ is a string field, the GETARGUMENTVALUES procedure finds that the method argument has value file:///florence.jpg. Since a replace operation is requested, the BUILDFUNCTION procedure generates field transformer $\phi_{file:///florence.jpg}$. Using the fact that $data$ is the third field (Line 2 of Figure 2(c)), it generates function $\{id \times id \times \phi_{file:///florence.jpg} \times id\}$.

Considering argument 1: replace mimeType, the solver finds that there are two possible values for the mimeType variable. Thus, Lines 9-14 of the algorithm yield function $\{id \times id \times \phi_{(image/png)} \times id \times id \times id \times \phi_{(image/jpg)}\}$, where Line 14 utilizes the definition of the $\cup$ operator on $F$ from Section V. Finally, Line 17 of Algorithm 1 composes the two functions given by Equations (4) and (5), which yields: $\{id \times id \times \phi_{(image/png)} \times \phi_{(image/jpg)}\} \times \phi_{(image/*)}\}$.

C. Fixed Point Iteration

Let us consider method sendMessage() from Figure 2(b). So far, we have assumed that the value of the Uri $uri$ at Line 8 of Figure 2(c) is available when we generate field transformers for $intent$. In reality, it is not initially available, because when we solve the problem for the first time, values for $intent$ and $uri$ are computed in the same iteration. Thus, in order to fully resolve all values, we run several iterations of the COAL solver. For example, in the first iteration, the transformer that is generated for statement $intent.setData(uri)$ is $\{\phi_{intent,1} \times \phi_{intent,2} \times \phi_{intent,3} \times \phi_{intent,4}\} = \{id \times id \times id \times \phi_{uri,1}\}$, where $\phi_{uri,1}$ is a transformer that indicates that the value of the $data$ field of $intent$ refers to the first field of Uri $uri$. We initially start with $\phi_{intent,1}$ and $\phi_{uri,1}$ mapping to $\omega$, for $1 \leq i \leq 4$. We then iterate until a fixed point is reached for $\phi_{intent,1}$ and $\phi_{uri,1}$. The same process allows the solver to resolve the value of $intent$ at Line 11 of Figure 2(b).

VII. APPLICATION TO ANDROID ICC

As an application of the COAL language and solver, we built IC3 (Inter-Component Communication analysis with COAL), an ICC inference tool that is based on COAL specifications. The main ICC classes are Intents, Intent Filters and URIs. For completeness we also model the Component Name, Bundle, Pending Intent and Uri Builder classes since they are referenced by the main class types.

Recall from Figure 3 that as a prerequisite to the MVC constant propagation, it is necessary to generate an inter-
mediate representation (IR) that is suitable to generate an ICFG. The COAL solver is currently implemented using the Soot framework [39] and the Heros IDE solver [3]. Soot converts Java bytecode to an internal IR that is recognized by its Spark [23] call graph construction module, which is used to build an ICFG. However, Android applications present additional challenges. First, they are distributed in a platform-specific bytecode format. We therefore preprocess them with Dare [30], which converts Android to Java bytecode. Second, Android applications are composed of components that may be started in an arbitrary order. Additionally, they are event-based programs that declare callbacks that may be called in an arbitrary order. In order to address this challenge in a conservative manner, we adopt the call graph construction procedure from FlowDroid [1], which generates a wrapper entry point method that simulates the application lifecycle and the arbitrary event and component call order.

The COAL solver takes aliasing into account. When a method modifies a variable \( o_1 \) that is a possible alias for another object \( o_2 \), our analysis generates two values for \( o_2 \). One of them takes the call into account and the other one does not. The one that does not models the case where the alias analysis results in a false positive (i.e., detecting that a value may point to a certain heap location even though it does not). This is similar to the standard idea of weak updates [7].

A. String Analysis

Strings are ubiquitous in Android applications. Many arguments to ICC methods are strings. Because of the limited set of predefined Intent fields (e.g., default action and category strings), in many cases, the value of string fields is determined by a finite set of constants. However, the way these constants are transferred or combined is not trivial and a string analysis is required to determine the set of possible values that a given variable can have. Our string analysis determines a safe overapproximation of such sets. It was inspired by JSA [9], although our analysis is highly customized for the purposes of Android. Conversely, JSA is more generic but significantly slower for our purposes. Our analysis works in two stages: constraint generation and constraint solving. Constraint generation simply gathers the dataflow facts for string variables. Constraint solving determines regular sets (described as regular expressions) that satisfy the constraints.

In the first stage we generate constraints for all string operations, modeling the String and StringBuilder classes. Our goal is to have a representation that can be used either by a constraint solver or by abstract interpretation. This is why the constraints are a symbolic representation of the original program operations. The analysis is flow-sensitive. Constraints model idioms that are common in Android operations: concatenation, string fields, function calls, etc.

In the second stage, a solver uses the constraints to answer queries about variable values. As a proof of concept, we implemented a simple solver that given a variable \( x \) produces a regular expression that overapproximates the set of values that \( x \) can take. It works by finding the constraints associated with \( x \) and by traversing the flow graph and interpreting the nodes. We avoid non-termination by detecting self dependence cycles and widening to \( .^* \) (that is \( \perp \)). Similarly, we widen to \( .^* \) when we detect calls to functions outside the analysis (for which we have not generated constraints). Although our widening method may be less accurate than that in [9], our simple solver is faster and can still be more accurate because of context sensitivity. Our analysis is interprocedural, context-sensitive, flow-sensitive, field-sensitive but not object-sensitive. Additional details about the string analysis can be found in the technical report [31].

B. Evaluation

The evaluation of our approach was aimed at answering three central questions:

**Q1:** Can IC3 precisely infer field values of ICC objects?

**Q2:** As an application of our analysis, how precisely can ICC messages be matched with their targets?

**Q3:** Are the computational costs of IC3 feasible in practice?

The answer to these questions determines how effectively our analysis can be used as the basis of inter-component analyses. Highlights of our evaluation are:

- IC3 infers precise field values for 85% of ICC values. Epiccc can only infer 66%. This is a significant increase in precision.
- When matching components that may communicate with one another, specifications from IC3 lead to 78% fewer component links than the current state-of-the-art.
- On average, our analysis takes 140 seconds per application. This makes it feasible in practice to use our analysis as the first step of inter-component analyses.

For performance reasons, we generally do not allow the constant propagation to analyze the Android framework code. The only exception is when a framework class may create or modify ICC objects, which only occurs in a few classes of the framework. In the few cases where ICC method arguments are not strings of characters (e.g., integer arguments), we use a simple analysis that looks for definitions of constant values for that argument. It simply traverses the interprocedural control flow graph starting at the method call, keeping track of all possible values. When a constant value cannot be found, a special \( \omega \) value is conservatively returned.

We performed our experiments on a corpus of 500 applications. They were randomly selected from a set of 453,525 applications downloaded from the Google Play store between January and September 2013. Some application could not be processed because of insufficient memory errors or timeout, so we report numbers for 460 applications.

**Precision of field values** - We first measured the precision of the fields of the ICC values inferred by IC3 at program points of interest (i.e., sending a message, or programmatically registering a component with an Intent Filter). The list of these program points is given in [31]. We counted the number of ICC values inferred by IC3 and Epiccc [34] for which no field value used for Intent or URI resolution is completely unknown (e.g., a \( .^* \) string value). We modified Epiccc such that it used the same entry point construction procedure from [1]. The precision results are presented in Table I. The third line shows the results for Intents and Intent Filters, whereas the fourth line shows statistics for URIs. The value count column shows the
We observe that the precision of the values inferred by IC3 for Intents, Intent Filters and URIs was high, with 85% of values being detected accurately by our tool. Epcc, on the other hand, could only precisely detect 66%. Of the 915 Intent and Filter values that IC3 detected precisely but Epcc did not, 591 were due to the presence of URI data in Intent values, which is not handled by Epcc. In 4 cases, Epcc missed a value that IC3 did not. The remaining 324 cases that were precisely detected by IC3 and not by Epcc were due to the more powerful string analysis. There was also a clear difference in the case of URIs, with IC3 precisely determining 374 values, compared to 176 for Epcc. That is because Epcc does not include a thorough model for URIs. In particular, a number of methods refer to other modeled objects. Since this is handled in an ad hoc manner in Epcc, good coverage of these methods cannot be achieved, resulting in a lot of missed values. On the other hand, using COAL specifications, IC3 achieves much better coverage of URI methods. In particular, references to modeled values are handled in a principled and generic manner. Finally, IC3 detected 73 fewer URI values imprecisely than Epcc, thanks to our new string analysis.

There are several reasons why IC3 missed 132 ICC values. First, some API callback methods have Intent or URI arguments that cannot be known statically. For example, method `onReceive()` is a Broadcast Receiver callback that is called upon reception of an Intent. The received Intent is passed as an argument to that method by the framework upon activation of the Receiver. The value of that Intent is in general impossible to determine statically. We found 48 such cases. Another related case was when URIs were extracted from Intents that were callback arguments with the `getData()` method, before being used to address Content Providers. Another cause for missed ICC values was when Intents were extracted from containers such as sets or lists. We will investigate handling these by tracking the values of these containers in future work. We note that handling containers is challenging, especially if tracking array indices is desired. Finally, we found a few pathological cases where a call to an interface or abstract method returning an Intent was not resolved to the proper possible subtypes by the call graph construction procedure.

In the 747 cases where imprecise values were inferred, the arguments to ICC API methods could not be determined. Some cases are not yet handled by our argument analyses (e.g., integer fields and string array fields), while other cases cannot be determined statically (e.g., sequences of complex string operations). We will continue investigating the cases that can be resolved while keeping good performance.

**Component matching** - As an application of inferring ICC values, we matched the computed Intents with potential target components for the 460 applications. This is a fundamental application of the ICC analysis, since the matching is necessary for any inter-component analysis. Matching precision determines the precision of the overall analysis. Its influence on analysis precision is similar to the influence of the call graph construction process in interprocedural program analyses: an imprecise call graph results in an overall imprecise analysis.

We implemented a matching process that was modeled after the Android Intent resolution process. We performed the matching using both the values computed by IC3 and those calculated by Epcc. Matching Intent-sending program locations with potential target components using values output by IC3 produced 26,872 links. In contrast, the matching that used Epcc values yielded 120,817 links. When performing inter-component analysis, fewer potential links imply fewer false positives (since the ICC value computation and matching are conservative). The 78% reduction in potential targets is a very significant gain in precision. The reason why a 19% gain in ICC value precision resulted in a 78% gain in matching precision is that imprecise ICC values often cause an explosion of the number of potential links. For example, when the action of an Intent is not known, the matching process conservatively matches it with all Intent Filter action values.

**Performance** - Processing all the applications took 64,571 seconds using our tool, or slightly less than 18 hours of compute time. That is about 140 seconds per application on average. The processing time was dominated by the IDE problem solver and the string solver, taking 73% of the time overall. The second most time-consuming function was the entry point building procedure of [1], taking 20% of the total time. Soot analyses (class loading, type inference, final call graph construction, etc.) took 4% of the time. Other parts of the analysis (e.g., COAL model parsing, result generation) took 3% of the total time. We did not find any clear trend describing how running time grows with size parameters of the input program. We leave this matter for future work.

**VIII. Discussion**

Writing COAL specifications requires some effort, which could be seen as a limitation. However, the effort to write a specification is much less than the effort required to produce separate data flow models for each object. We have also found that it is less prone to errors. Finally, handling cases where modeled objects reference other modeled objects in a principled way (for example see Lines 12 and 22 of Figure 2(c)) has allowed us to model complex inter-object relationships such as the one between Android Uri, UriBuilder and Intent. We estimate that writing specifications for all modifiers and

</table>

Writing COAL specifications requires some effort, which could be seen as a limitation. However, the effort to write a specification is much less than the effort required to produce separate data flow models for each object. We have also found that it is less prone to errors. Finally, handling cases where modeled objects reference other modeled objects in a principled way (for example see Lines 12 and 22 of Figure 2(c)) has allowed us to model complex inter-object relationships such as the one between Android Uri, UriBuilder and Intent. We estimate that writing specifications for all modifiers and
queries for Android took us approximately five hours using the developer documentation for the classes involved. On the other hand, writing ad hoc composite constant propagation models for Epicc took longer than eight hours for each modeled object, with an incomplete coverage. In order to make writing specifications more effortless, we are looking into a semi-automated inference approach. We believe that COAL elements such as the list of fields, many modifiers and sources as well as queries can be inferred automatically.

We have successfully applied composite constant propagation to Android ICC, but it can also be applied to other problems where object values have to be inferred. In order to ensure that this is the case, the COAL solver can be extended by registering new COAL keywords for field operations and field types. This enables support for additional operations beyond add, remove, replace and clear, as well as for additional method argument analyses.

Our evaluation does not compute the number of spurious values that would be computed if we were not keeping track of the correlations between fields. We expect that, similarly to any analysis refinement, this will be useful in some contexts more than others. In future work, we will quantify the precision benefit and potential performance penalty of keeping track of field correlations over traditional constant propagation. We will also compare our results with values from dynamic traces.

IC3 has the traditional limitations of static analysis on Java. It does not handle native code or reflection. Some approaches [4] exist that can handle reflection for Java programs and could be adapted for Android. Loops and recursion are naturally handled for the operations that we defined (i.e., add, remove, clear and replace) because the corresponding field transformers are idempotent for composition. Other operations (e.g., appending to a list) would require carefully defining the composition of the corresponding field transformers.

IX. RELATED WORK

Single-valued interprocedural constant propagation has been studied in the past [6], [16], [27], [36]. Unlike our work, for each constant these works seek to find a single value that is common to all interprocedural paths. Multi-valued constant propagation [2], [26] has also been studied. While our constant propagation is also multi-valued, it propagates composite types. As we explain in Section III, it is possible to simply consider fields to be separate, single variables. However, this approach limits the precision of the results.

We are not the first to consider tuples of values in the context of static analysis. Several works have used tuples or vectors to represent properties of sets of sets of variables [10], [19], [20], keeping track of correlations between properties of different variables. Our analysis is more restricted in that it only handles correlations between object fields. However, our goal is different: we aim to provide analysis designers with a relatively easy-to-use layer of abstraction to statically compute possible object values without having to write data flow functions. This has enabled us to write a thorough model of Android ICC with limited effort. We hope that it will allow other analysis designers to quickly prototype and run composite constant propagation analyses in various contexts.

Analysis of Inter-Component Communication in Android has been performed in past work. Dynamic analysis has attempted to enforce security policies related to ICC [5], [12]. Other work has performed inter-component dynamic taint analysis [13]. Static analysis has also been investigated. ComDroid [8] attempts to determine a limited number of properties of Intents. Epicc [34] is the first work that tried to determine most Intent attributes that are useful for component matching. It performs some ad hoc composite constant propagation, which is considerably more complex than writing COAL specifications. Another important difference is how we deal with cases where modeled classes reference other modeled types. Epicc deals with them in an ad hoc, class-specific manner. On the other hand, our iterative algorithm described in Section VI-C is completely generic and can apply to all occurrences of modeled value references. As a result, we can model all of ICC in Android. However, like Epicc, our analysis is context-sensitive and flow-sensitive.

Apposcopy [15] uses static analysis as the basis of a signature-based malware detection system. The static analysis includes some ICC analysis limited to a subset of the Intent fields. In particular, URI data is not considered.

String analysis reasons about the set of values for string variables. While much work has been performed in this area [9], [17], [21], [28], [37], [40], JSA [9] is the closest to our analysis. However, JSA seeks to model all string operations, whereas we limit our analysis to the most common cases. Additionally, while JSA performs its own pointer analysis, we rely on the more efficient Spark [23] analysis, which is already performed as part of the ICFG building process. As a result, our analysis is much more efficient in the context of Android ICC analysis. Initial tests with JSA showed processing times well over an hour for medium sized applications, which made the entire ICC analysis impractical.

X. CONCLUSION

In this paper, we introduced the MVC constant propagation problem, and we presented the COAL language and the associated solver for MVC problems. We also developed IC3, an Android ICC analysis tool that is based on a reduction to an MVC problem. As a part of IC3, we developed a sound string analysis that offers an effective tradeoff of scalability and precision. We achieved a much greater accuracy in ICC inference than previous work. In the future we plan to investigate more ways to improve accuracy, and to what extent generating COAL specifications can be automated. Finally, we will apply our IC3 work to design novel inter-component analyses in Android.
